Determining the Net Present Value of Timber Investments and Comparing Investments of Different Rotations¹

Andres Susaeta and Chris Demers²

The economic valuation of forests is necessary for several reasons. For example, value of a forest operation can be used to determine the sale or purchase price of a forest during a commercial transaction or the amount of taxes owed to the IRS when selling timber or the forest. Accurate economic valuation is essential for comparisons of different pine or hardwood species rotation ages and/or different management intensities, as well as to determine the insurance value of a forest. Another important purpose of an economic assessment is to compare different timberland investments. This is particularly important when timber management projects have different time horizons. For example, would a forest landowner be economically better off growing a forest for pulpwood production with a short rotation instead of growing the same forest for sawtimber production with a longer rotation? In this publication, we will provide the standard methods used to conduct a comparative analysis of timber investments of similar or unequal time horizons, namely the net present value (NPV) approach and the equivalent annuity approach (EAA), respectively.

The Net Present Value (NPV) Approach for Projects of Equal Length

The NPV determines the difference between the present value of cash inflows of timber benefits and the present value of cash outflows of silvicultural and management costs over a period of time. The timber benefits are realized in the future when the forest stand is thinned or finally harvested, and some silvicultural costs and management costs can be also incurred in the future as the forest stand is growing. Therefore, both costs and returns need to be discounted back to the present over T years of the forest stand. A discount rate (also called interest rate to take into account the time value of money) is decided on to solve for NPV. If we consider a single rotation of T years, the net present value (NPV) of a forest stand for timber production can be defined as:

$$NPV = PVB - PVC \quad (1)$$

2. Andres Susaeta, assistant research scientist; and Chris Demers, forest stewardship coordinator, School of Forest Resources and Conservation; UF/IFAS Extension, Gainesville, FL 32611.

where PVB and PVC are the present value of the sum of timber benefits and sum of costs, respectively, since the establishment of the forest stand until the forest stand is clearcut. The PVB and PVC can be represented as follows:

$$PCB = \sum_{t=1}^T \frac{A_t}{(1+r)^t}$$

$$PVC = C_0 + \sum_{t=1}^T \frac{C_t}{(1+r)^t} + C_i \left[\frac{(1+r)^T - 1}{r(1+r)^T} \right] \quad (2)$$

Where A_t is the economic revenues due to thinning benefits and final harvest of the stand; C_0 is the establishment costs (site preparation and planting costs at stand age 0); C_t is the intermediate costs to grow the stand at time t (e.g., fertilization, marking, thinning costs); C_i is the annual management or administrative costs; r is the discount rate; and T is the final harvest age.

Let's consider the following forest investments in slash pine and loblolly pine stands (Table 1). It is assumed that the slash pine and loblolly pine stands are planted at time $t = 0$ and harvested at age $T = 25$ years. Both stands produce three forest products: sawtimber, chip-and-saw, and pulpwood. Silvicultural activities, with their associated current costs and revenues (cash flows), occur at the times specified in Table 1. A discount rate $r = 0.05$ (5%) is also assumed.

Table 1. Costs and Revenues (\$ per acre) of Silvicultural Activities in Slash and Loblolly Pine Stands.

Activity	Age (years)	Revenue (cost) \$ per acre	
		slash	loblolly
Establishment	0	(400)	(400)
Fertilization	5, 15	(70), (70)	(70), (70)
Thinning	15	232	363
Annual costs	1–20	(20)	(20)
Final harvest	25	4490	4432
Prices of sawtimber (\$27.0), chip-and-saw (\$18.9) and pulpwood (\$10.4) per ton obtained from Timber Mart South (2018). Yields of sawtimber, chip-and-saw and pulpwood for slash pine and loblolly pine are provided by Pienaar et al. (1996) and Harrison and Borders (1996), respectively. Cost of thinnings is assumed to be 20% of the stumpage prices. Thinning yields (slash) of 4.7 (chip-and-saw) and 18.9 (pulpwood) tons per acre; thinning yields (loblolly) of 11.7 (chip-and-saw) and 21.3 tons (pulpwood) per acre (loblolly). Harvest yields (slash) of 85.0 (sawtimber), 98.5 (chip-and-saw) and 22.5 (pulpwood) tons per acre; harvest yields (loblolly) of 208.8 (sawtimber), 80.3 (chip-and-saw) and 100.1 (pulpwood) tons per acre.			

The NPV of single rotation for timber production is: (see Table 2)

Following the NPV criterion, timber investment in loblolly pine is preferred over a timber investment in slash pine because NPV associated with loblolly pine (\$731 per acre) is higher than the NPV associated with slash pine (\$667 per acre).

The Equivalent Annuity Approach (EAA) for Projects of Unequal Length

The equivalent annuity approach (EAA) is a method used to evaluate the economic viability of two or more timber investment projects of different lengths. It basically puts NPV on an annualized basis. The EAA is defined as follows:

$$EAA = \frac{r \times NPV}{(1 - (1+r)^{-T})} \quad (3)$$

Example (a): let's assume a slash pine timber investment with an NPV of \$672 per acre over a 26-year rotation and a loblolly pine timber investment with an NPV of \$721 per acre over a 23-year rotation. Is the slash pine investment better than the loblolly pine investment? In our example,

$$EAA \text{ (slash)} = 0.05 \times 672 / (1 [1.05]^{-26}) = \$46.7$$

$$EAA \text{ (loblolly)} = 0.05 \times 721 / (1 [1.05]^{-23}) = \$53.5$$

Following the EAA criterion, the loblolly pine project is a better option.

Example (b): is a slash pine investment with a NPV of \$667 per acre with a rotation age of 25 years a better economic alternative compared to a loblolly pine investment with a NPV of \$612 per acre rotation age of 30 years? Example:

$$EAA \text{ (slash)} = 0.05 \times 667 / (1 [1.05]^{-25}) = \$47.3$$

$$EAA \text{ (loblolly)} = 0.05 \times 612 / (1 [1.05]^{-30}) = \$39.8$$

Therefore, it is better to invest in slash pine management.

Example (c): let's assume, and just for practical purposes, that a loblolly pine project is a riskier investment compared to a slash pine project. This is reflected by a higher discount rate– $r=0.07$. With a 7% discount rate, the *NPV* of a loblolly pine investment is \$108 per acre over a 30 year rotation. The slash pine investment is the same as in example (b) ($EAA=\$47.3$). Under this new assumption,

$$(\text{loblolly}) = 0.07 \times 108 / (1 [1.07]^{-30}) = \$8.7$$

It is clear that it is not worth investing in loblolly pine and waiting the additional 5 years. Furthermore, we can see that a higher discount rate severely reduces the *NPV* and *EAA* of the loblolly pine investment. Compared to the loblolly pine investment in example (b), the *NPV* and *EAA* are reduced by \$508 per acre and \$30, respectively.

Conclusions

The net present value (*NPV*) of a single rotation of a forest stand provides the criterion to choose between different forest project investments of equal lives (equal rotation ages). This approach suggests that the best forest investment project is the one that yields the greatest *NPV*. The equivalent annuity approach (*EAA*) is employed when forest project investments have different time lengths. Similar to the *NPV* approach, this criterion indicates that the best forest investment project is the one that yields the highest *EAA*. Because the discount rate can affect the *NPV* and *EAA* values, it must be chosen wisely. In many cases one may use at least two discount rates to look at the discount rate change effect on *NPV* or *EAA*.
