Identification for Florida's Citrus-Growing Regions

extended periods of flooding. For additional soils information, see flooding. Wet soils are poorly drained, chronically wet, or subject to citrange, and trifoliate orange rootstocks. Generally unsuitable for Swingle citrumelo, Carrizo citrange, and other citrumelo, Clay soil also suffer stresses related to high bicarbonate in the irrigation water. Calcium-induced Fe chlorosis. New evidence suggested that HLB-affected trees may water.

This rating indicates how much a given rootstock can tolerate high-salinity irrigation. Refers to a relative rating based on US market size standards. Comparisons of rootstocks for effects on tree yield should consider canopy size. Small trees usually produce less fruit per tree than larger trees, but the smaller trees can be planted at higher densities.

Yield/tree. This term is related to the amount of fruit on an individual mature tree at a recommended spacing but recognizing that the bearing habits of different scion-rootstock combinations vary. For example, some are more precocious (early bearing) than others. Comparisons of rootstocks for effects on tree yield should consider canopy size. Small trees usually produce less fruit per tree than larger trees, but the smaller trees can be planted at higher densities.

Yield/acre. Yield per tree times the number of trees per acre will ultimately determine the yield per acre. Generally, the relationship between these two variables (yield per tree and yield per acre) is directly proportional. However, there are situations where a tree has only intermediate yield per tree because of a smaller canopy but yield per acre is high because more trees of smaller stature can be planted per acre.

Juice quality. Brix/acid ratio rating has been determined from juice samples from various rootstock and scion combinations and compared to industry averages.

Salinity. Salty waters in Florida containing high levels of NaCl are problematic because rootstocks vary in their absorbance and translocation of the Na+ and Cl- ions. This rating indicates how much a given rootstock can tolerate high-salinity irrigation water.

High pH. Rootstocks vary in their tolerance of calcareous soils mostly because of the CaCO3 in the soil and/or the irrigation water. Such conditions commonly lead to calcium-induced Fe chlorosis. New evidence suggested that HLB-affected trees may also suffer stresses related to high bicarbonate in the irrigation water.

Clay soil. Refers to soils with horizons containing >20% clay or loamy materials, and especially soils where such horizons are close to the soil surface. These soils are generally unsuitable for Swingle citrumelo, Carrizo citrange, and other citrumelo, citrange, and trifoliate orange rootstocks.

Wet soil (flooding). Wet soils are poorly drained, chronically wet, or subject to extended periods of flooding. For additional soils information, see Field Guide to Soil Identification for Florida’s Citrus-Growing Regions, SP 362 (http://ifasbooks.ifas.ufl.edu/p-266-field-guide-to-soil-identification-for-floridas-citrus-growing-regions.aspx).

Drought. With the advent of generally practiced irrigation, drought is no longer considered an important rootstock factor.

Freezes. The threat of a severely damaging cold event remains. Few severe freeze events have occurred since the 1980s. Thus, the tolerance of many of the minor and recently released rootstocks has not been adequately determined.

HLB (Huanglongbing) incidence. Observations are accumulating that the incidence of HLB is less among trees on some rootstocks, especially new rootstocks included in various field trials. This rating reflects those observations; however, the ratings are quite tentative and subject to change. The interpretation of the observations is speculative and highly subject to revision over time. Survey results from a grower-scale observation of HLB incidence among commercial scions and rootstocks are available by visiting http://www.crec.ifas.ufl.edu/extension/pdf/hlb_scion_survey.pdf.

Blight. As with HLB, rootstock tolerance to blight, a disorder of unknown cause, is based on field observation in research trials and commercial groves. It is a combined rating for overall incidence and rate and time to first losses. Thus, Cleopatra mandarin is rated “5 T” because while the incidence of blight is low among young trees, substantial losses can occur when the trees reach 12 to 15 years of age.

Phytophthora nicotianae ratings are a combination of foot- and root-rot tolerances that are similar within a rootstock, but may differ; for example, sour orange has good foot-rot tolerance but mediocre root-rot tolerance. P. palmivora/Diaprepes weevil complex. Rootstocks vary in their tolerance to P. nicotianae and P. palmivora, but when P. palmivora is present, it is not ordinarily problem unless Diaprepes weevils are also present (Phytophthora/Diaprepes Complex). Most rootstocks are susceptible to this complex, but the ratings may vary depending on soil type.

Burrowing nematodes. All rootstocks are susceptible except for selections of Carrizo citrange, Ridge Pineapple sweet orange, Milam lemon, and Kuharske citrange.

Citrus nematodes. Trifoliate orange has tolerance to citrus nematodes. That trait is inherited by many of its hybrids including Swingle citrumelo. Sting nematode is a pest in some instances, especially in soils with high sand content. There are no known tolerant rootstocks.

Xyloporosis and Exocortis. These virus and viroid diseases, respectively, can be problematic for trees on certain rootstocks. However, they have been virtually eliminated from Florida because of clean budwood programs. Therefore, they are not included in this guide.

Tristeza. This disease is caused by an aphid-transmitted virus. Rating rootstocks is a bit complicated because there are strains and mixtures of strains of this virus that cause symptoms ranging from very mild effects to tree decline.

Additional Comments

Incompatibility. There are just a few situations where a scion/rootstock combination, like Murcott budded to Carrizo citrange or Swingle citrumelo, declines from an apparent incompatibility that manifests itself at the bud union. Other problematic combinations were described by Garnsey et al. and are listed in the citations on the interactive website.

WARNING! Mandarins are perhaps the most sensitive scions to incompatibility, especially with trifoliate orange hybrid rootstocks. Nursery managers and growers should be alert to the fact that new releases of mandarin scion types have generally not been tested for compatibility with a broad range of rootstocks.

How to Use the Rootstock Selection Guide

[1] General

The rootstock information provided is a broad based compilation of Florida information collected from field trials and commercial situations. The information is general in nature as it represents essentially “average” rootstock behavior across a range of conditions related mostly to scion variety and site conditions. The quality of information varies due primarily to the time period of evaluation. Thus, the rootstocks have been grouped accordingly into three categories: 1) MOST USED, which are commercial rootstocks with a long history of use and are the ones for which the descriptions are the most reliable (highlighted in blue); 2) MINOR USE rootstocks, which are ones that have been in minor commercial use for a while and others that were prominent at one time but whose importance has faded as newer rootstocks were introduced and adopted commercially (highlighted in green). The information presented for most of the rootstocks in this category is reliable but is sometimes not as fully developed as with the most used commercial rootstocks; and 3) RECENTLY RELEASED rootstocks, which were more recently created in breeding programs and have been under evaluation in Florida for only a few years (highlighted in yellow), eventually selected from field trials and small commercial cooperative trials. Recently released rootstocks have limited commercial experience. It is also important to note that in rating rootstocks, the differences for a stated factor are sometimes based on a quasi-qualitative comparison and in other cases a more quantitative basis. Tree height, for example, is essentially a relative rating based on the standard of comparison: a tree on a rootstock rated as “Large” would be equivalent in height to a mature tree on rough lemon rootstock. On the other hand, a rootstock’s rating regarding citrus nematode or Phytophthora tolerance is fundamentally based on quantitative screening trials plus commercial experience.

[2] Year of First Commercial Availability

The year of first commercial availability is when the rootstock first appeared in the nursery use records of the Florida Department of Agriculture & Consumer Services, Division of Plant Industry, Bureau of Citrus Budwood Registration. Information on rootstock use can be found in the annual reports of the Bureau available at this site: http://www.freshfromflorida.com/Divisions-Offices/Plant-Industry/Bureaus-and-Services/Bureau-of-Budwood-Registration.

[3] Horticultural Traits

Seed germination. Germination is the growth of a seed into a young plant or a seedling. This parameter is important for plant propagation in the nursery. Some rootstocks, like Bank Citrange and 1584, have a high seed germination rate (80%–90%) but usually produce fruit with few to no seeds.

William S. Castle, Kim D. Bowman, Jude W. Gasser, Rhuanto S. Ferrarezi, Stephen H. Futch, and Steve Rogers

Key to Symbols

- Blue—Commercial; Green—Minor Commercial; Yellow—Recently Released
- G—Good, P—Poor, H—High, I—Intermediate, L—Low, lg—Large, R—Resistant, S—Susceptible, Sm—Small, T—Tolerant, Blank space—Rating unknown or undetermined, [ ]—Any symbol in brackets indicates a probable or expected rating, +/-—Relative ranking,
- UFR—University of Florida Rootstock, and US—USDA.

Footnotes: *Seed germination in the first year under appropriate storage conditions; **Produces few seeds; ***seedlings are highly variable.
