Introduction and Purpose

Residential construction activities can drastically alter soil physical, chemical, and biological properties, thereby affecting the growth and performance of landscape plants. Urban construction typically involves land clearing, use of heavy equipment, and importation of fill soils, all of which can negatively affect soil properties and lead to problems with plant establishment, growth, and aesthetic quality. Assessment of soil conditions before landscape installation can help identify problem areas and allow for amelioration of problems that may affect plant growth. Additionally, this assessment is useful for the selection of the most appropriate landscape plant species. This information will be useful to homeowners, turf managers, and lawn care service companies.

Soil Assessment

Preplant soil assessment allows for characterization of soil properties and the identification of major problems that may affect plant growth and quality. Upon completion of the soil assessment, you should have answers to the following questions:

1. What is the soil texture?
2. What is the soil pH/fertility status?
3. What were the natural soil conditions?
4. How disturbed is the soil?
5. What is the extent of soil compaction?
6. Are there soil drainage problems?
7. Is there a salinity issue?

What is the soil texture?

Soil texture is the relative proportion of sand, silt, and clay particles. In general, soils dominated by sand-sized particles are coarse-textured or sandy, soils dominated by silt-sized particles are moderate-textured or loamy, and soils dominated by clay-sized particles are fine-textured or clayey. In Florida, surface soils tend to fall in the sandy, loamy sand or sandy loam textural classes, which are located in the bottom left-hand corner of the textural triangle (Figure 1). Soil textural class can be determined in the laboratory or estimated by a trained soil scientist using a “feel” method. Knowledge of the soil texture...
Figure 1. The soil textural triangle is used to categorize soils based on the proportion of sand, silt, and clay particles. (Figure Credit: USDA-NRCS)

can provide clues about other important soil properties, such as water-holding capacity and fertility. For example, sandy soils are often well drained with low fertility, organic matter, and water-holding capacity. For more detailed information about soil texture and textural classes, see EDIS publication SL29/SS169: Soil Texture.

What is the soil pH/fertility status?

Soil pH affects the growth and quality of landscape plants by influencing the availability of nutrients and soil microbial processes. In acidic soils, the availability of plant nutrients such as potassium (K), calcium (Ca), and magnesium (Mg) is reduced, while the availability of potentially toxic elements such as aluminum (Al), iron (Fe), and zinc (Zn) are increased. In alkaline soils, iron, manganese (Mn), zinc, and boron (B) are commonly deficient. Maximum nutrient availability for most species occurs when soil pH is between 6.0 and 7.0.

The soil pH can be determined by sending a soil sample to a reputable testing laboratory such as the University of Florida Extension Soil Testing Laboratory (ESTL). The UF/IFAS ESTL website is http://soilslab.ifas.ufl.edu. Some county Extension offices also test soil for pH, and you can locate your local Extension office at http://solutionsforyourlife.ufl.edu/map/. For more information about soil sampling and testing (including instructions on how to take a soil sample), see EDIS publication SL281/SS494: Soil Sampling and Testing for the Home Landscape or Vegetable Garden.

The best advice regarding soil pH is to choose landscape plants that are suited for the natural pH of your landscape soil. There are soil additives that can raise or lower the pH of soils; however, the effects of these materials are often very short-lived. In addition, if your soil pH is within 0.4 of a pH unit of the ideal range, adjusting the pH will probably not improve plant performance. For more information about adjusting the pH of acidic and marginally alkaline soils, see EDIS publication SL256/SS480: Soil pH and the Home Landscape or Garden.

What were the natural soil conditions?

Construction activities often lead to significant changes in soil properties, making it difficult to determine the properties of the natural soil that existed before construction. Information about the native soil conditions may be useful with regard to site suitability and limitations. While some topsoil may be removed from sites before construction, the lower soil horizons may still be present or may have been incorporated into fill soil placed on the site after construction was completed. The soil survey, available either in print form or through the Web Soil Survey at http://websoilsurvey.nrcs.usda.gov/app/HomePage.htm, contains a description of the soil series and profile, general information about site suitability for various activities, as well as specific physical and chemical properties of the soil.

How disturbed are the soils?

During residential construction, topsoil is often removed from the site exposing the subsoil. Topsoil material may be stockpiled for future use at the site or removed completely.

Construction-related activities, such as the use of heavy equipment, the use of fill soil materials, and the installation of impervious surfaces can alter the physical properties of the exposed subsoil. The soil may be minimally disturbed (soil profile disturbed but not compacted), moderately disturbed (soil
profile disturbed and soil compacted), or completely unusable (soil characteristics or compaction level will inhibit plant growth). It is a good idea to take a soil core (Figure 2) or dig out a vertical slice from the disturbed soil; existing construction holes or trenches are useful for this purpose. Lay the soil core out on a flat surface, and compare the existing disturbed soil to the description of the native soil indicated on the site soil survey. This comparison will give you an idea of the kind of disturbance the site received during construction activities.

Figure 2. Removing a soil core or vertical slice from the disturbed soil to compare with the description of the native soil indicated on the site soil survey can provide information about the extent of soil disturbance during construction activities. (Photo Credit: Amy Shober, UF/IFAS)

**What is the extent of soil compaction?**

Compacted soils provide a stable foundation for homes, but they are not ideal for plant growth and water infiltration. In fact, it may be nearly impossible to establish plants in compacted soils. Soil compaction reduces the total number and size of air-filled pores, which are critical in supplying the plant roots with oxygen (Figure 3). Compaction can also increase resistance to root penetration, which can cause poor/shallow rooting and, in turn, poor plant growth. There is often an increased need for irrigation and fertilization in compacted soils because of the limitations to plant growth encountered under compacted conditions. Poor plant growth in compacted soils can also require replacement of dead or declining plant material, often at additional cost to the homeowner or landscape professional.

Figure 3. Soil compaction occurs, then soil particles are compressed, and the pore space between particles decreases. (Figure Credit: Geoff Denny)

The level of soil compaction can be determined by measuring soil bulk density. Soil bulk density is the mass of dry soil per unit volume (e.g., grams per cubic centimeter) and accounts for the spaces between the soil particles (pore space) as well as the soil solids. Soils with a high proportion of pore space have low bulk densities and vice versa. Bulk density may range from normal (approximately 1.4 g cm\(^{-3}\)) to extremely packed (2.2 g cm\(^{-3}\)) in urban mineral soils. Soil bulk density can be estimated in the field using the following steps (adapted from Lichter and Costello 1994):

1. Weigh bucket or container.
2. Dig a 12-inch-deep hole, and place all soil in container.
3. Determine volume of hole: Line the hole with a plastic bag and fill the bag with water; then measure the volume of water in the bag.
4. Place soil in an oven for several days at 180 to 200°F until completely dry, or dry in a microwave for 2–4 min., then cool for 1 min. until it reaches a constant weight.
5. Weigh the dried soil.

Archival copy: for current recommendations see http://edis.ifas.ufl.edu or your local extension office.
6. Calculate bulk density using the following equation:

\[
\text{Bulk density} = \frac{\text{weight of dry soil} - \text{weight of bucket or container}}{\text{volume of water}}.
\]

If the soil bulk density is higher than documented compaction threshold levels (Table 1), tillage methods or organic matter can be used to help reduce compaction and improve rooting. For more information about how to manage compacted soils, see EDIS publication SL317/SS529 Soil Compaction in the Urban Landscape.

Are there soil drainage problems?

Soil drainage problems can be a result of natural topography, soil grading during construction, or existing soil compaction. Areas of concern can be identified by noting low-lying areas in the landscape, areas where water collects after a rain, and areas that remain wet after the surrounding soil has drained. Actions, such as tillage and adding organic amendments, may alleviate drainage issues if compaction is the cause. Additionally, aeration with a soil core aerator (Figure 4) can help to moderately increase drainage in some situations. In cases where natural topography or poor soil grading activities result in poor drainage conditions, regrading the site may be necessary. Alternatively, the landscape design should take moderately wet or dry areas into account by choosing plant species tolerant of these conditions.

Is there a salinity issue?

High soil salinity may be a naturally occurring problem in coastal areas; however, the use of saline irrigation water or excessive fertilization may also lead to an accumulation of salts. High salt concentrations can cause soil structure problems, Mg and K deficiency, chloride toxicity (leaf burn), and root desiccation. Plants vary in their tolerance to soil salinity; therefore, it is important to assess the salinity of your soils so that you can correct the problem or select appropriate plant material. Salinity problems can be diagnosed by testing the electrical conductivity (EC) of the soil. Soil EC can be measured directly in the field with a special probe or in the lab (available by special request at the UF/IFAS ESTL). Soil EC will increase with increasing salt concentration. While the EC test can indicate a salt problem, it cannot provide information about the specific salts present in the soil. For more information about the methods for determining soil salinity and options for controlling or dealing with soil salinity, see EDIS publication SL262/MG447: Soils and Fertilizers for Master Gardeners: Tackling Soil Salinity Problems in the Home Landscape.

Landscape Design following Soil Assessment

Once the assessment is complete, you are ready to start your landscape design. Corrective actions should be considered to remedy major problems, such as soil compaction, so that the landscape design has the best chance of resulting in healthy plants and low maintenance. The simplest design strategy is to choose plant species that are tolerant of the soil conditions (e.g., pH, salinity, drainage) that are present after addressing any issues identified in this assessment.
