Abstract. One hundred modified Tedders traps were monitored weekly for 2.5 years in each of seven citrus orchards located throughout Florida. Temporal patterns of the prevalence of adult *Diaprepes abbreviatus* at each site were compared to determine the feasibility of using insect abundance in sentinel orchards to schedule pest management activities within a region. Weevil abundance in three orchards on Florida's central ridge exhibited no consistent temporal patterns between years or among sites. In three central and eastern flatwoods sites, the abundance of weevils tended to be highest during the spring and early summer, but the variation in this pattern was high between sites and years. The mean abundance of weevils

in the flatwoods sites was more than five-fold greater ($P = 0.02$) than that for sites on the central ridge. These data suggest the need for site-specific monitoring programs to aid in management of *D. abbreviatus*. Causes of regional variation in the abundance of *D. abbreviatus* merit additional research.

Diaprepes abbreviatus (Diaprepes root weevil) is a serious problem of widespread distribution within the Florida citrus industry infesting approximately 130,000 acres and costing in excess of 70 million dollars annually. Methods to determine the local abundance of the insect are limited and expensive. Many growers do not know when weevils are present in their grove or what the seasonal abundance is for their geographical area. Without this basic information, control tactics may be improperly implemented. Un-baited pyramidal traps, commonly referred to as 'Tedders traps', are sometimes employed to determine the seasonal abundance patterns of the weevils (Duncan et al., 2001). After emergence from the soil, the adults are attracted to any nonreflective silhouette; citrus tree trunks or other structures placed in the grove which simulates a tree trunk. Grower acceptance has been relatively poor due to the time and cost of regularly servicing and monitoring the traps. However, data from various studies have shown regional similarity in adult emergence and abundance on a seasonal basis. The objective of this study was to determine whether an area-wide scouting programs using Tedders traps to estimate the emergence and seasonal abundance of adults can assist growers in instituting control methods for this weevil.

This research was supported by the Florida Agricultural Experiment Station and by a grant from the USDA (Diaprepes Grant #727384112), and approved for publication as Journal Series No. N-02573.

Materials and Methods

A two and one-half year survey was implemented to estimate the seasonal abundance of adult *Diaprepes* root weevils using 100 un-baited pyramidal traps per location in six major regions in Florida. Three study sites were located on the Florida central ridge in Lake and Polk Counties, and four sites were in flatwoods conditions in DeSoto, Hendry, Indian River and Dade Counties. Florida's central ridge is characterized by deep, well drained sandy soils. Depth to groundwater is much less in the coastal and central "flatwoods" regions, where trees are generally grown on beds to increase the soil volume suitable for root growth. Soil texture and drainage characteristics vary greatly among flatwoods sites. Initially, all sites were commercially producing citrus groves, known to be infested with *Diaprepes* for four to six years and were irrigated with low volume microsprinkler irrigation systems. The Indian River and Dade County sites were changed to other locations after the first year of the study. The original Indian River site was replaced with another citrus grove which was under the same management whereas the Dade County site was relocated to

an ornamental tree nursery. Site descriptions, sample areas and trap spacings are given in Table 1.

Data was collected by grower cooperators who reported the number of weevils captured in each trap during each previous seven-day period. Graphical data summaries were posted weekly at www.lal.ufl.edu/diaprepes/diaprepesemergence.htm and were freely available to growers who were informed about the survey through extension citrus newsletters, magazines and meetings.

Soil samples from each site were processed to determine the particle size distribution. Oven-dried samples (100 g) were dispersed in a dilute alkaline solution of sodium metaphosphate on a mechanical shaker overnight and rinsed thoroughly on a 0.053 mm opening sieve to remove silt and clay particles. Soil remaining on the sieve was dried, mechanically shaken on a nested series of sieves (0.053, 0.106, 0.25, 0.5, 1.0 mm; Rototap RX-29, W.S. Tyler, Mentor, Ohio), and fractions retained by each were weighed. Relationships between weevil abundance and soil particle size classes at each site were investigated by graphical examination and calculation of linear correlation coefficients.

Table 1. Basic site information per location for the *Diaprepes* emergence study.

| Grove factor | County site location | | | | | | |
|--------------------------------------|--|--|-----------------|--|--|---|--|
| | Lake | Polk 1 | Polk 2 | Indian River | DeSoto | Hendry | Dade |
| Variety | Valencia | Hamlin & Pineapple | mixed | Red grapefruit, switched to different location in yr 2 | Hamlin | Sunburst & Fallglo | Yr. 1—Red grapefruit, yr. 2 ornamental nursery |
| Rootstock | Carrizo | mixed, lemon, Swingle and Carrizo | mixed | yr. 1, sour orange yr. 2 mixed rootstocks | sour orange/ bittersweet | Swingle | |
| Irrigation | micro-sprinkler, 10 gph or less | micro-sprinkler | micro-sprinkler | micro-sprinkler, 10 gph per tree | micro-sprinkler, 23 gph per tree | micro-sprinkler | micro-sprinkler, but limited use |
| Year planted | 1985 | 1950s with inter-planted in the 70s & 80s | 1960s | yr. 1, 1979, yr. 2 mid 90 | 1990 | 1992 | 1990s |
| Year infested | 1998 | early 1990s | mid 1990s | 1994 or 95 | 1997 or 98 | 1995 +/- | unknown |
| Soil type | Astatula sand | Sparr sand & Mill-hopper fine sand | | Winder fine sand | Ona and Smyrna | Boca and Chobee | Krome—mixture of marel & Rockdale |
| Spacing | 15' × 25', no beds | 15' × 30' with variation | 12.5' × 25' | 12' × 25', two row beds | 10' × 25', four row beds | 12.5' × 25', two row beds | 12.5' × 25', flat planting with limited mounds for each tree |
| 2001-02 Yield estimate, (boxes/acre) | 400 boxes in better grove area with around 200 in poor areas | 400 +/- | | est. 350, not harvested due to size and economic factors | 675 | 319 Sunburst, 448 Fallglo | not harvested due to canker rules and economics |
| Percent resets | 90% mature trees | none within the last 3 years | | 1-2% | minimum 8%, some tree loss due to citrus tristeza virus | few | few |
| General grove conditions, comments | Test area varies in condition with well drained soils in better condition, part of the test area is near a water hole with poor drainage and is in poor condition. | The grove is in slightly less than average condition for the area. | | Grove was in average condition, but removed due to low fruit prices. The grove was removed in May of 2002 and scheduled to be replanted in June or July of 2002. | The grove is in average condition for area with some foliage thinning. | Grove condition varies within block, better drained soil is in better condition than poorly drained soil. | Grove is in poor condition with little inputs for pest or nutritional care, little weed control. |

Results and Discussion

Although locations were known to have been infested with *Diaprepes* for at least four to six years, the emergence patterns and average weevils collected per trap varied greatly between the study sites. Previous reports have indicated that although adult emergence and abundance can vary throughout the year the primary emergence period is normally in April to mid-July and/or late-August to mid-October (McCoy et al., 2004). Data from this study agrees with year round presence; however, the patterns often differed from discreet spring and fall peaks of abundance. Following is a brief discussion of seasonal abundance patterns for each of the three well-drained sites in Lake and Polk locations (Fig. 1).

Lake County. Weevil abundance increased from early May 2001 until mid July when numbers peaked following a major rain event of greater than 6 inches in a one week period. This spike was somewhat like an event at the DeSoto location below. Nigg et al. (2003) also reported that adult weevil emergence in a central Florida citrus orchard was initiated following the onset of the summer rains in July, following an unusually dry spring and early summer. After July, the weevil abundance remained relatively low (<0.1 weevils per trap per week) for the remainder of the survey year. Abundance during 2002 remained low the entire year at less than 0.1 weevils per trap per week until the fall when weevil capture increased somewhat from Nov. until Feb. 2003. Thereafter, weevil abundance remained low until the survey terminated in October.

Polk County 1. This location had the lowest weevil population (<0.1 weevils per trap) of any of the six survey sites. Weevil populations declined from May 2001 until September when they increased slightly. Very few weevils were captured early in 2002, until April. As in Lake County weevil abundance increased in autumn of 2002 and highest numbers occurred in December. The number of weevils declined sharply in Jan. 2003 and increased gradually thereafter. This grove was known to be infested with weevils for more than six years and is in a location where many other groves are infested with weevils.

Polk County 2. Trapping at the second Polk County site occurred from May 2002 until Nov. 2003 and weevil abundance was low throughout the survey. Populations were slightly higher in May-June and Dec. 2002 and may have increased briefly in Sept. 2003.

The less well-drained sites which are typical of the flatwoods and east coast areas include DeSoto, Hendry and Indian River (Fig. 2).

DeSoto. The first major peak in abundance occurred from May through July 2001 followed by a steady decline in numbers for the remainder of the year. An interesting event occurred in early July 2001 when heavy rains occurred which triggered a major emergence totaling 2.14 weevils per trap for the weekly period (not shown). These heavy rains (12 inches in two weeks) cause localized short term flooding within the grove for several days. This event indicates that a large number of mature weevils can be in the soil and will emerge when forced or encouraged to emerge based upon environmental or other factors (Nigg et al., 2003). Weevil abundance remained relatively low (<0.1 weevils per trap) until May 2002. After July the numbers of weevils declined for the remainder of the year. Abundance again increased in March of 2003 with peak emergence in April then declining somewhat into the summer.

Hendry County. This location had the highest average weevil levels among the seven sites. Weevil abundance was high in

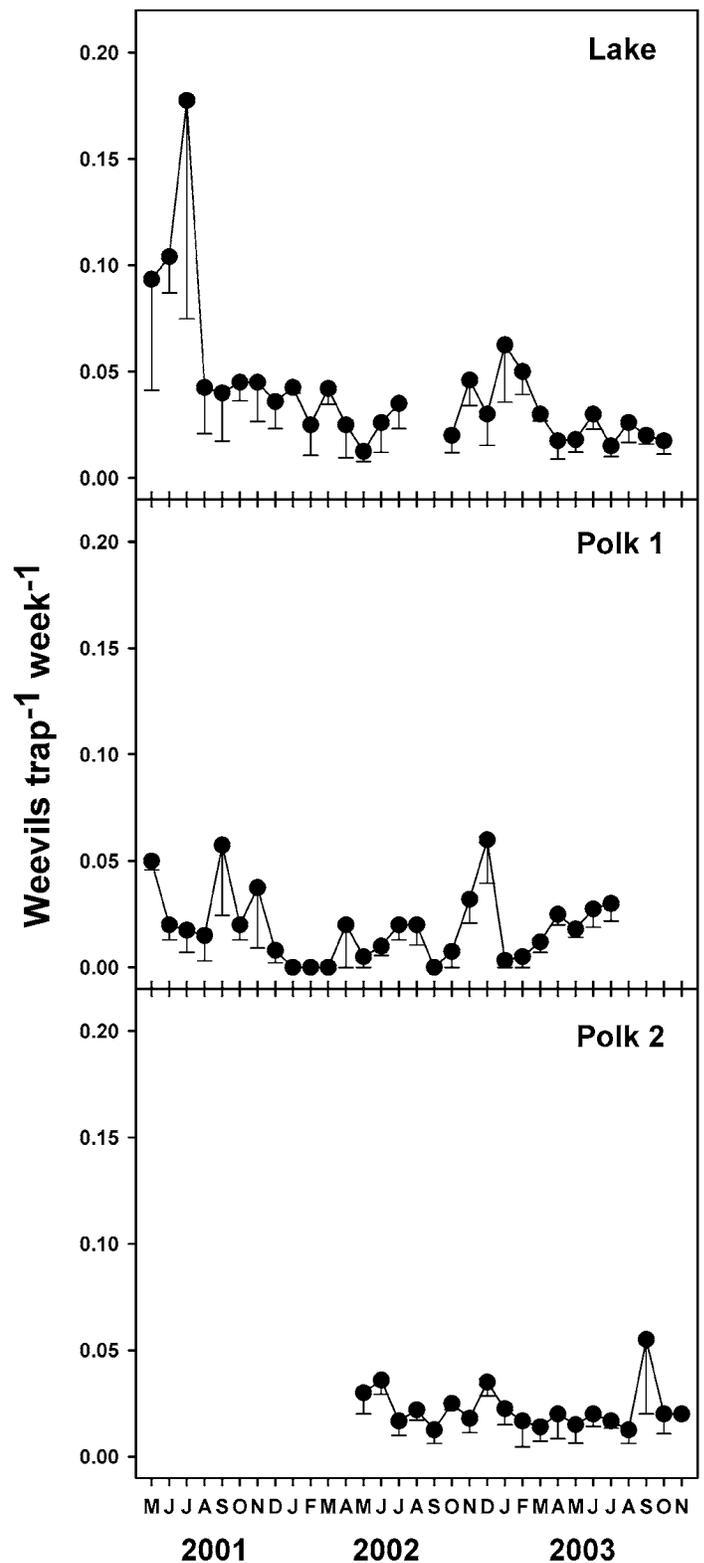

Fig. 1. Average numbers of *Diaprepes abbreviatus* collected per trap each week during 31 months in three citrus orchards on the central ridge of Florida. Weekly data for each month were averaged to better illustrate seasonal patterns. Error bars are standard errors of the mean.

April 2001 at the beginning of the study (>0.5 weevils per trap) and decreased steadily for the remainder of 2001. In 2002 abundance began to increase in January with peak re-

covery in March and April and then declined for the remainder of the year. In 2003 weevil abundance followed a similar pattern, peaking in March and gradually declining thereafter.

Indian River County. Emergence at this location was extremely low (<0.04 weevils per trap) from the beginning of the survey in early April 2001 until December. This pattern did not follow the trends of the other flatwoods locations. Beginning in mid Dec. 2001, abundance began to increase until mid April and then began to decline in late April 2002 when this grapefruit grove was removed due to small fruit size and low fruit prices. The grove was in good horticultural conditions at the time of tree removal. The site was replaced with a grove in the same general area in Oct. 2002. At the new site, abundance increased in December 2002 with peak emergence in Jan. 2003, then declined until April when population levels increased somewhat until June.

Dade County. The abundance pattern varied from 0 to 0.15 weevils per trap per week but lacked any major or strong emergence patterns during 2001 (Fig. 3). Weevils were trapped throughout the year at low levels. Since the location was receiving limited care (irrigation and nutritional inputs) this could have limited the flushing cycle of the trees thereby reducing or limiting weevil numbers. Peak abundance occurred in June and July 2002. This site was replaced in September 2002 with an ornamental site that supported higher numbers of weevils. Emergence peaked at the ornamental site in January and again in August 2003.

The average weekly abundance of weevils was more than five-fold greater ($P = 0.02$) in the flatwoods sites (DeSoto, Hendry, Indian River Counties) than in those on the central ridge (Lake and Polk Counties) (Fig. 4). Adult weevil numbers were highest at the DeSoto and Hendry and followed by Indian River locations. This regional trend for weevil population pressure is consistent with previous reports, although the causes of variation in weevil numbers between sites is unknown (Adair, 1994; Duncan et al., 2001; Stansly et al., 1997). Duncan et al. (2003) reported greater natural control of *D. abbreviatus* by entomopathogenic nematodes in an orchard

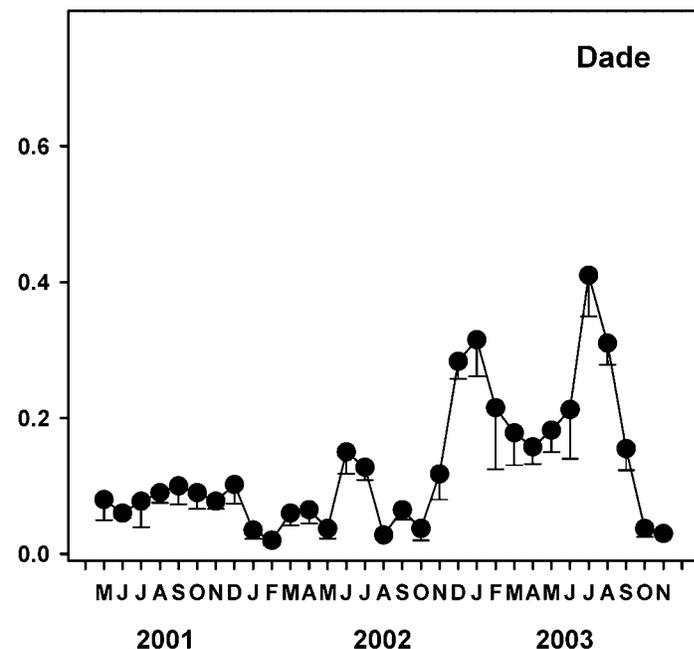

Fig. 3. Average numbers of *Diaprepes abbreviatus* collected per trap each week during 31 months in a citrus orchard in Dade County Florida. Weekly data for each month were averaged to better illustrate seasonal patterns. Error bars are standard errors of the mean.

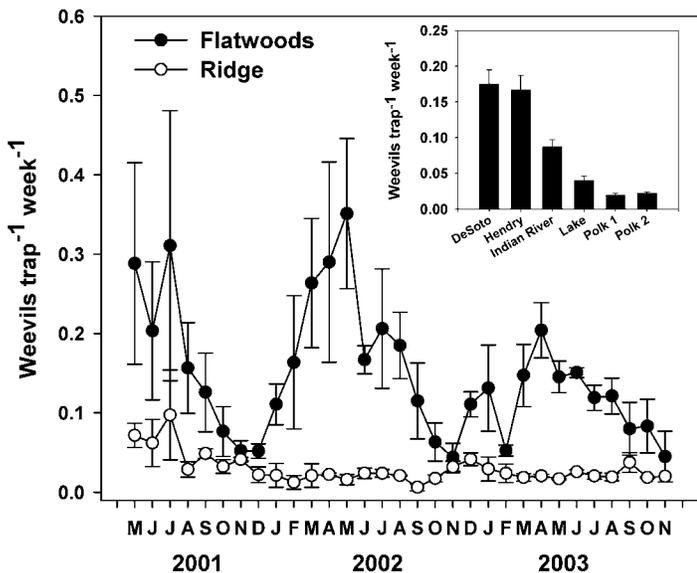

Fig. 4. Average numbers of *Diaprepes abbreviatus* collected per trap each week during 31 months in three citrus orchards in flatwoods regions and three orchards on the central ridge of Florida. Weekly data for each month were averaged to better illustrate seasonal patterns. Inset shows the tree-year average for each grove used in the study. Error bars are standard errors of the mean.

on coarse sandy soil on the ridge compared to one on sandy clay loam in the flatwoods. However, we detected no relationships when weevil abundance was plotted against the proportions of any of the sand particle sizes and linear correlation coefficients between abundance and soil particle sizes were not significant ($P > 0.10$).

When data were pooled within region, weevil abundance was highest in the spring to mid-summer (March-July) of each year in the flatwoods, which is consistent with other reports (Adair, 1994; Duncan et al., 2001). Seasonal abundance was not apparent for the pooled data from the ridge sites, although abundance has been reported to increase consistently in the spring and occasionally in the autumn from individual sites on the ridge (Duncan et al., 2001).

Conclusions

While population trends within each geographical region should be somewhat similar, the temporal abundance of weevils varied significantly with location. Weevil pressure tended to be higher in flatwoods orchards compared to those on the central ridge.

This website provided an easily accessible source of timely information of weevil abundance trends in selected sites. Knowledge of these population patterns may help growers anticipate seasonal weevil population growth in order to time management strategies more effectively; however, management decisions should be based on supplemental observations regarding site-specific population levels. Data for the entire study is available on the web at: www.lal.ufl.edu/diaprepes/diaprepesemergence.htm.
